#### Abstract

The aim of this brief narrative review is to summarize the present evidence, provide recommendations for data analysis, and appropriate training methods to reduce strength and power asymmetries within athlete populations. Present evidence shows that a strong interest in the assessment of asymmetry exists. Despite the perceived associated relationship between asymmetry and injury and performance, a clear link is still missing. Practitioners need to be aware of this when they decide to assess asymmetries and later design training interventions. Several bilateral and unilateral tests could be used to assess asymmetries such as isokinetic dynamometry, the isometric mid-thigh pull, squat and Nordic hamstring exercise. Based on the current evidence, future investigations require further standardization of methodology and analysis to optimize interpretation (e.g., within session and between session), adoption, and implementation of inter-limb asymmetry testing and appropriate interventions. In this review three training interventions have been proposed to reduce existing lower limb asymmetries in sport populations: traditional resistance training, flywheel resistance training, and combined training interventions, with some evidence suggesting such interventions can reduce lower limb asymmetries. Nonetheless, the number and quality of articles currently available are too limited to draw firm conclusions, therefore, further research is needed to verify whether training interventions can achieve these aims. To develop an understanding and application of interventions addressing inter-limb asymmetries within the sport, greater methodological rigor should be applied towards study design, data analysis and interpretation of future investigations as well as when appraising the current literature.

**Keywords:** resistance training, performance, jump, flywheel, injury, sport.

#### 75 INTRODUCTION

76 Understanding the complex nature of sport-specific tasks and quantifying the physical 77 capacities that underpin them are of significant interest to the sports science community (6,12). 78 Specifically, analysis of inter-limb asymmetries on injury burden, it's use in return to sport, 79 and relationship with sport performance has received much attention (13,22,35,44). 80 Investigating inter-limb asymmetries consists of comparisons between dominant and non-81 dominant, stronger and weaker, or injured and non-injured limbs (6,12). Assessment of 82 physical capacity (*i.e.*, strength, jumping, power, balance, range of motion, etc.) is frequently 83 performed and ranges widely in sport (22). The assessment of asymmetries has grown from 84 singular time point "snap shots" to a more dynamic process (i.e., longitudinal monitoring) that 85 accounts for direction of asymmetry and differences between bilateral and unilateral deficits 86 (9,15). Nonetheless, little can be done with asymmetry data if analysis and interpretation is 87 inappropriate (28). The question: "Practically, what should be done with a, e.g., 5, 14, or 19% 88 inter-limb asymmetry?" remains a difficult one to answer. Appraisal of the present evidence is 89 limited by the varied definitions of asymmetry and its associated importance towards both 90 injury and performance (13,35). Indeed, many questions remain about how such values should 91 be interpreted to stand a chance of bringing about actionable change. Regarding tests employed, 92 several jump and strength tests have been devised for the evaluation of inter-limb asymmetry 93 and are often used as key criterion markers alongside performance parameters with athletes 94 that are either healthy or returning to sport after injury (22,51). Given the importance of lower 95 limb strength and power for athletic populations (8), the assessment of asymmetry for these 96 physical capacities seems especially relevant and valid.

97

98 The use of jump testing in elite sport has proliferated because it provides easily accessible, 99 cheap and valuable inter-limb asymmetry data (51). Such information is often considered when 100 aiming to reduce likelihood of injury or re-injury during rehabilitation with athletes (12,53). In 101 fact, unilateral jump tests (i.e., repeated unilateral hopping) have been validated to quantify 102 inter-limb differences that are often key during the rehabilitation process but are also relevant 103 to independent markers of sport performance (33,44). Specifically, larger unilateral 104 countermovement jump (CMJ) asymmetries have previously been associated with worse 105 acceleration and sprint performance in youth female and youth male team-sport athletes 106 (18,30). In addition, greater asymmetry during unilateral drop jumps have also been related to 107 inferior change of direction (COD) and sprint performance in adult female soccer players (21). 108 Nonetheless, within the same investigation, no association between larger unilateral CMJ

109 asymmetry and worse COD and sprint performance existed (21). Similarly, higher levels of 110 unilateral vertical jump asymmetry in professional female soccer players did not impair speed 111 nor power performance (42). Where adult males are concerned, small inter-limb asymmetries 112 in distance hopped appear to have no association with reduced COD or multi-directional speed 113 performance (41). In agreement with the aforementioned findings, no consistent associations 114 between jump asymmetries and COD or sprint performance of elite youth (U18 and U23s) 115 soccer players were found over the duration of a soccer season (14). Thus, it seems apparent 116 that the link between jump asymmetries and sport-specific skills or performance is not 117 consistently evidenced and needs to be further investigated (22).

118

119 Assessment of inter-limb strength asymmetries are particularly important because they can 120 potentially help identify athletes at risk of adopting dysfunctional or ineffective movement 121 patterns that negatively impact performance (12,22). Inter-limb strength asymmetry testing can 122 be performed with a variety of equipment ranging from isokinetic dynamometers to 123 assessments of exercises (*i.e.*, back squat) with force-plates (12). A relationship between larger 124 lower limb peak force asymmetries and reduced overall strength (13) as well as impaired sport 125 specific kicking ability has been previously reported (32). Interestingly, some evidence 126 suggests that sub-elite and youth athletes present larger inter-limb strength asymmetries than 127 elite athlete populations (12,59). Although youth athletes have shown to present greater 128 asymmetries, the literature also suggests that such asymmetries are not guaranteed to negatively 129 impact athletic performance (54). The variation in the present literature may be related to the 130 fact that sporting tasks are underpinned by multiple physical qualities and involve high levels 131 of skill rather than solely rely on strength, power, and inter-limb asymmetries. Finally, it is 132 important to consider that due to the associative designs of the aforementioned studies, it is not 133 possible to infer a cause-and-effect relationship. In fact, future investigations should prioritize 134 whether training interventions may induce specific changes in asymmetry and establish 135 whether reducing such asymmetry meaningfully directly improves performance of sporting 136 tasks.

137

Although the need for investigation into the link between asymmetries and sport performance is clearly needed, a great deal of consideration must be made for the methodology, analysis, and interpretation of inter-limb asymmetries to validate the findings of future investigations. In fact, the present literature lacks clarity on the optimal way to assess, analyze, and reduce (strength and power) inter-limb asymmetries with athletes. Therefore, the aim of this brief narrative review is to summarize the present evidence, provide recommendations for data
analysis, and appropriate training methods to reduce strength and power asymmetries within
athlete populations.

146

148

### 147 ASSESSMENT OF ASYMMETRIES AND DATA ANALYSIS

## 149 Assessing inter-limb asymmetry

Assessment of physical capacities and asymmetries should be dictated by the needs analysis of the sport and athlete in question (13,22,35,44). Once they are determined, if it is deemed that assessing and monitoring asymmetry holds additional value for the practitioner, then it can be integrated into the routine monitoring process. Whilst almost any physical quality can be assessed for asymmetry (provided separate dominant and non-dominant limb data can be obtained), much of the literature appears to have focused on strength and jumping tasks, and as such, this section will focus on these physical capacities (6,11,12,15,24).

157

158 Asymmetry in strength tasks. Numerous methods have been used to assess lower limb inter-159 limb asymmetry in strength such as isokinetic dynamometry (12,24,56), isometric mid-thigh 160 pull and squat (13,27,32), or even compound movements such as the back squat itself (57) and 161 Nordic hamstring exercise (NHE) (23). Isokinetic dynamometry of the lower limbs can provide 162 a detailed profile of asymmetry, given between-limb data can be obtained for both the 163 quadriceps and hamstrings at varying speeds of movement (6). This notion of varying 164 contraction speeds is useful if practitioners want to bias an assessment towards either force or 165 velocity. Furthermore, previous research has shown excellent reliability for the assessment of 166 peak torque, when assessing flexion and extension both concentrically and eccentrically at 167 60°/s (ICC = 0.93-0.95), 180°/s (ICC = 0.93-0.96), 240°/s (ICC = 0.93-0.95) and 300°/s (ICC = 168 0.82-0.97) (2,37,58). However, the use of this equipment is largely confined to a laboratory, 169 making this unfeasible for many practitioners. Instead, asymmetry data can be obtained from 170 iso-weight devices (e.g., back squat and leg-press using free-weights or stack machines), which 171 are commonly used in strength and conditioning programs (13,22). The use of these devices 172 enables data to be collected during training sessions, which would increase the external validity 173 of such assessments; furthermore, iso-weight testing methods have reported excellent 174 reliability scores (generally, ICC > 0.90) (31,47). Another method to assess asymmetries 175 requires the utilization of twin force plates, which are needed to gather separate data for each 176 limb. In this case, the isometric mid-thigh pull and squat can be performed and offer 177 information about lower limbs asymmetries (13,27,32). Although this approach is valid, it may

178 not always be practical or possible for some practitioners who do not have such technology. In 179 contrast, only a single force platform is needed if a unilateral assessment method is chosen 180 (e.g., unilateral isometric mid-thigh pull or squat), which provides an understanding of 181 maximal force production capabilities. Further to this, previous research using these methods 182 have shown that larger asymmetries in peak force are associated with reduced overall strength 183 levels (13) and accuracy in kicking (32). However, whilst a variety of metrics can be obtained 184 from these two assessments (e.g., peak force, impulse and rate of force development at different 185 time intervals), the only consistent and reliable metric appears to be peak force, when assessing 186 unilaterally (ICC = 0.93-0.97; CV = 4.15-5.70%) (17).

187

188 Practitioners may choose to assess eccentric strength in athletes for several reasons, but mainly, 189 for improving performance and reducing the likelihood of injury (4,46). One common method 190 is to assess asymmetries during the NHE, however, the current information is somewhat 191 limited. Cuthbert et al. (25) compared the NHE to three other isometric hamstring strength 192 assessments and found that the NHE showed the best between-session reliability (coefficient 193 of variation (CV = 2.89-4.01%) compared to other methods (CV = 6.27-10.23%). In addition, 194 the Kappa coefficient statistic, which is used to highlight consistency in the "direction of 195 asymmetry" between test sessions, reported that the NHE demonstrated substantial levels of 196 agreement (K = 0.62) compared to *slight* to *moderate* levels of agreement for the other methods 197 (K = 0.03 - 0.47) (25). The current evidence, although studies on strength asymmetry are limited, 198 suggests that the unilateral isometric mid-thigh pull or squat tests, and the NHE can be used as 199 valid tests to assess lower limb strength asymmetries.

200

201 Asymmetry in jumping and lower limb power tasks. Similar to strength, a wide variety of 202 jumping tasks can assess inter-limb asymmetries. For example, countermovement jumps 203 (CMJ) (7,34), drop jumps (45) and a variety of horizontal hopping (continuous unilateral 204 jumping) tasks (13,16) have all been previously employed, each of which has shown acceptable 205 reliability data both bilaterally and unilaterally (ICC = 0.68-0.99; CV = 2.82-9.18) in a number 206 of studies (9,13,14,16). Since inherent differences between jumping tasks (stretch-shortening) 207 cycle function and plane of movement) exist, not all jump tests (and asymmetry analysis) are 208 suitable for practitioners, who ultimately, should select the most appropriate test based on the 209 sport of their athletes. Apart from consideration for the needs of the sport, two key points should 210 be considered when selecting jump tests for the detection of inter-limb differences. The first

relates to whether the test is unilateral or bilateral in nature, while the second point is relatedto the specific characteristics of the task.

213

214 1) Bilateral vs. unilateral jumping. Although both could be relevant for practitioners, these 215 tests offer different information. For example, bilateral jumps (since two limbs are involved in 216 the task) allow for greater (total) power outputs, jump height, concentric and eccentric velocity 217 than unilateral jumps. Logically, bilateral jumps could be preferentially used in sports where 218 such bilateral movements are more common (e.g., volleyball). While unilateral tasks may not 219 allow for force and power compensation between the limbs during the task (since only one 220 limb is used at time), unilateral jumps may be a better measure of "actual limb capacity" and 221 therefore, potentially more sensitive at detecting asymmetries (20). To support the notion that 222 differences exist between these two tests, previous research has shown that the direction of 223 asymmetry revealed *poor* levels of agreement (all Kappa values < 0) between bilateral and 224 unilateral CMJ for mean force, concentric and eccentric impulse (11). Furthermore, key 225 differences between such tests have been recently reported showing that bilateral and unilateral 226 CMJs present different limb dominance characteristics and practitioners should avoid using 227 one test to represent the other (10). An asymmetry measured during a bilateral task may be 228 masked by some athlete's compensation strategies, whilst an asymmetry measured unilaterally 229 may be considered more of an imbalance in jumping capacity.

230

231 2) Asymmetry is highly task and metric-specific in nature. An abundance of literature reports 232 that asymmetries between tasks are unlikely to be matched (11,22,38,48,60). Simply put, if an 233 asymmetry of 5% or 10% is achieved in a given test, it should not be assumed that the same or 234 similar values would be achieved in another test. Additionally, although group mean data rarely 235 changes significantly between test sessions, analysis of individual data shows that asymmetries 236 can vary considerably between sessions (15,25). Thus, individual, rather than group analysis, 237 has been recommended for asymmetry assessments (13). Additionally, asymmetry is almost 238 always computed and presented as a percentage value. However, it is not always apparent as 239 to what this value represents, often requiring further explanation for practitioners.

240 241

243

242 Data analysis for inter-limb asymmetry

Regardless of testing outcome, use of asymmetry data may differ slightly within a single session in comparison to multiple sessions. This section will provide the practitioner with some suggestions on how to meaningfully interpret an individual's inter-limb asymmetry data in bothscenarios.

248

Within-session analysis. Asymmetry should only be considered "real" if the between-limb percentage value is greater than the intra-limb variability assessed with a CV (28) – a concept that has been employed recently (13,19). If an athlete exhibits a real asymmetry, it may not require an immediate intervention to correct the imbalance. However, awareness of persistent real asymmetries (i.e., repeated test sessions over time) may highlight potential limb capacity issues that may need to be addressed (44).

255

256 Between-session analysis. During test-retest designs or longitudinal analyses, comparing 257 changes in asymmetry to the baseline CV values would confirm whether changes in the signal 258 (asymmetry) are greater than the noise (baseline CV). When assessing percentage change, the 259 difference (between time points) is typically computed relative to where it came from (i.e., 260 baseline) (13,19). A second point of consideration relates to the direction of asymmetry: it is 261 important to remember that asymmetry is a ratio, making it comprised of two individual parts 262 (i.e., dominant and non-dominant limb scores). Thus, when practitioners treat asymmetry as a 263 single number, no context is provided for which limb performed superiorly. The Kappa 264 coefficient statistic enables analysis of the levels of agreement for the direction of asymmetry 265 (i.e., limb dominance) between test sessions (25). This concept can be simply explained with 266 the following example: if an athlete jumps higher on their dominant leg initially, the next 267 testing session will aim to establish (regardless of the magnitude of asymmetry) whether the 268 dominant limb is still outperforming the non-dominant side. Intuitively, practitioners may not 269 think any obvious reason exists as to why this should fluctuate between test sessions, especially 270 if no training intervention has been conducted. However, recent evidence has shown that levels 271 of agreement are far from perfect between test sessions (15,25), indicating that: 1) fluctuations 272 in limb dominance may be a naturally occurring phenomenon and, 2) the reliability of 273 asymmetry of some tests may be low, therefore, practitioners should verify the reliability of 274 their tests before incorporating them in to their routine monitoring process. Although clear 275 guidelines on the treatment of asymmetries are currently unavailable, it is the authors' opinion 276 that athletes who exhibit consistent limb dominance patterns over time may need specific 277 targeted training interventions while athletes that show these natural fluctuations between limbs 278 may not need any specific intervention.

280 The link to a YouTube video of how to compute the Kappa coefficient in Microsoft Excel is 281 reported in the supplementary material.

282

#### 283

## **RESISTANCE TRAINING METHODS FOR REDUCING ASYMMETRIES**

284

#### 285 Traditional resistance training methods

286 A recent meta-analysis by Bettariga et al. (8) investigated the effects of training interventions 287 on inter-limb asymmetries, measured across a range of physical performance tests. In summary, 288 the asymmetry tests most commonly used to demonstrate changes in side-to-side differences 289 are a range of unilateral jump and change of direction (COD) speed tests. When training 290 methods are considered, the majority of traditional resistance programs have utilized a 291 combination of strength and jumping based exercises over a period of 6-10 weeks.

292

293 For example, Bazyler et al. (26) used 20 recreational strength trained males to perform a 294 bilateral back squat training intervention, consisting of 6 sets of 3-5 repetitions ranging from 295 85-92% of 1 repetition maximum (1RM), twice a week for 7 weeks, with the second session 296 having a 10-15% drop-off in intensity each week. Isometric peak force asymmetry was 297 measured at 90 and 120° knee angles on twin force plates, with the group sub-divided into 298 strong (n = 10; 1RM back squat = 168 kg) and weak (n = 10; 1RM back squat = 138 kg) groups, 299 pre-intervention. The strong group started the intervention almost perfectly symmetrical ( $\leq$ 300 2.2%) and thus, showed no meaningful change in asymmetry post intervention. However, the 301 weak group showed significant reductions in asymmetry at both 90° (P = 0.045;  $3.9 \rightarrow 1.9\%$ ) 302 and  $120^{\circ}$  (P = 0.007; 4.6  $\rightarrow$  3.9%) conditions (26). Intuitively, practitioners may think that 303 unilateral-based exercises should be prioritized to reduce lower limb asymmetries; however, it 304 seems that consistent training using the back squat may also be a possible means of minimizing 305 existing side-to-side differences. Pardos-Mainer et al., (2020) investigated the effects of two 306 weekly strength and power training sessions over an 8 week period in female soccer players 307 (49). In this study, a short-term in-season combined strength and power training program 308 induced greater speed and COD performance improvements than soccer training alone in 309 adolescent female soccer players, however, no variations in interlimb-asymmetry tests were 310 reported (P > 0.05; effect size [ES]: -0.13 to 0.57). Although this study reported improvement 311 in sport performance, it was not suitable to reduce inter limb-asymmetry, which highlights that 312 more research is needed to verify the validity of strength and power training programs to reduce

any existing imbalances. Currently, we do not have strong evidence in support of traditionaltraining interventions, which should be considered in future study designs.

315

## 316 Flywheel resistance training methods

317 Although flywheel training has been investigated with a variety of populations relating to 318 strength, power, and athletic performance (1,5,52,55) – less is known about its efficacy in 319 reducing inter-limb asymmetries (8,40). Flywheel training exercises ranging from (bilateral, 320 unilateral, lateral) squats to multi-directional movements have been applied with the objective 321 of reducing inter-limb asymmetries (29,39,43). Madruga-Parera et al. (35) reported that sixteen 322 sessions of multi-directional flywheel training over 8 weeks enhanced sport-specific 323 performance (i.e., change of direction [COD] and jump) but did not reduce asymmetry. 324 Meanwhile, weekly lateral squat training sessions over 10 weeks improved jump height 325 asymmetry and CMJ performance (29). However, the present literature is limited to youth male 326 athletes and may not appropriately represent the effects of flywheel training on inter-limb 327 asymmetries in elite athletes or female populations (40). Additionally, the training 328 implemented may not have been ideal for achieving eccentric overload (43), which is an 329 important feature of flywheel training (3). In particular, the ability to produce demanding 330 eccentric phases may be particularly important for developing strength, optimizing 331 performance, and potentially reducing inter-limb asymmetries (3,8,40). Although multi-332 directional and lateral flywheel exercises both improved sport performance parameters, their 333 impact on inter-limb asymmetry is not as clear. In agreement with the aforementioned 334 inconclusive results, no clear relationships exist between asymmetry parameters (COD, 335 flywheel lateral squat power, or jump) and sport performance measures (sprint or jump) in 336 youth soccer players (54). The current flywheel literature highlights an unclear link between 337 the performance of athletic tasks and inter-limb asymmetry during flywheel training in sporting 338 populations.

339

### 340 *Combined training interventions*

Dello Iacono et al. (2016) investigated the effects of core stability training on unilateral CMJ height asymmetry in 20 adolescent soccer players (36). For the intervention group, CMJ height asymmetry was reduced from 5.4 to 1.6% (P = 0.001; ES = 2.01), whilst the imbalance in the control group increased from 4.8 to 7.2% (ES = 1.28). Intuitively, whilst this reduction in asymmetry may seem favorable, a closer inspection of the training program shows that whilst some core-based exercises were programmed (e.g., seated torso rotation and kneeling 347 superman's), so too was some more fundamental strength exercises (e.g., the NHE and walking 348 lunges), in addition to maximal effort 5-m accelerations. Therefore, it seems likely that 349 reductions in jump height asymmetry could be attributable to strengthening the lower body, 350 rather than exclusively to core-based exercises.

351 Another research group used the FIFA 11+ program twice a week for 10 weeks with female 352 soccer players aiming to improve physical performance and reduce inter-limb asymmetries 353 (50). This study reported changes in unilateral broad jump asymmetry distance, unilateral CMJ 354 height, and COD time during two different tests but no meaningful changes in asymmetry were 355 evident for any test (P > 0.05). Although it is of significant interest, the current evidence 356 supporting the use of training methodologies to reduce strength and power asymmetries with 357 athletic populations is limited and unclear. Currently, the most appropriate strategy to manage 358 strength and power asymmetries with athletes appears to be consistent application of resistance 359 training methods to improve strength and subsequently reduce underlying imbalances.

## LIMITATIONS AND FUTURE DIRECTIONS

366

367 This review is not without limitations, the first limitation is related to the link between some 368 asymmetry tests (e.g., jumps) and sport-specific skills or performance, which is not consistently 369 evidenced and needs to be further investigated (22). Future investigations should aim to 370 determine whether improving imbalances between limbs actually enhances key performance 371 parameters or reduces likelihood of injury concurrently. A second limitation is related to the 372 inconsistency that is frequently found between asymmetry scores using different tests. For 373 example, an asymmetry could be detected using one lower limb test but may not be detected 374 using another assessment. This type of inconsistency in the evaluation of lower limb 375 asymmetries could be explained by the very nature that asymmetry scores are test specific and 376 should not be, therefore, inferred from other tests. Finally, and relating to previous suggestions 377 regarding data analysis for asymmetry: an individual approach that considers the magnitude of 378 asymmetry relative to the CV; and consistency in the direction of asymmetry is likely needed 379 on a case-by-case basis, to better understand the relevance of any existing inter-limb 380 differences. However, further research is needed to verify the general reliability of asymmetry

tests (e.g., ICC and CV) as well as the consistency of tests to evaluate the direction of lowerlimb asymmetries.

383

### 384 CONCLUSIONS

385 The aim of this brief narrative review was to summarize current assessment methods, data 386 analysis, and exercise interventions for reducing lower limb strength and power asymmetries 387 with athletic populations. It is clear from the existing evidence that a strong interest in the 388 assessment of asymmetry exists because of the associated importance relative to both injury 389 and performance. Despite this, a clear link is missing, therefore practitioners need to be aware 390 of this when they decide to assess asymmetries and later design training interventions that may 391 in part, be influenced by such asymmetries. Currently, several bilateral and unilateral tests that 392 could be used to assess asymmetries such as isokinetic dynamometry, the isometric mid-thigh 393 pull, squat and NHE. Based on the current evidence, future investigations require further 394 standardization of methodology and analysis to optimize interpretation (e.g., within session 395 and between session), adoption, and implementation of inter-limb asymmetry testing and 396 appropriate interventions. Regarding the use of intervention protocols to reduce existing lower 397 limb asymmetries in sport populations, based off the limited evidence to date, it seems logical 398 to suggest that consistent strength training over time, may be a valid method for reducing any 399 existing inter-limb asymmetries. Furthermore, given the accepted importance of strength 400 training for both improving athletic performance and reducing non-contact injuries, this seems 401 like a sensible suggestion for practitioners to keep in mind. In this review three training 402 interventions have been proposed: traditional resistance training, flywheel resistance training 403 and combined training interventions, with some evidence suggesting such interventions can 404 reduce lower limb asymmetries. Nonetheless, the number and quality of articles currently 405 available are too limited to draw firm conclusions. Therefore, further research is needed to 406 verify whether training interventions can achieve these aims. To develop an understanding and 407 application of interventions addressing inter-limb asymmetries within the sport, greater 408 methodological rigor should be applied towards study design, data analysis and interpretation 409 of future investigations as well as when appraising the current literature.
